Analyzing the genetic structure of populations

Introduction

So far we’ve focused on inbreeding as one important way that populations may fail to mate at random, but there’s another way in which virtually all populations and species fail to mate at random. Individuals tend to mate with those that are nearby. Even within a fairly small area, phenomena like nearest neighbor pollination in flowering plants or home-site fidelity in animals can cause mates to be selected in a geographically non-random way. What are the population genetic consequences of this form of non-random mating?

Well, if you think about it a little, you can probably figure it out. Since individuals that occur close to one another tend to be more genetically similar than those that occur far apart, the impacts of local mating will mimic those of inbreeding within a single, well-mixed population.

A numerical example

For example, suppose we have two subpopulations of green lacewings, one of which occurs in forests the other of which occurs in adjacent meadows.\(^1\) Suppose further that within each subpopulation mating occurs completely at random, but that there is no mating between forest and meadow individuals. Suppose we’ve determined allele frequencies in each population at a locus coding for phosglucoisomerase (PGI), which conveniently has only two alleles. The frequency of \(A_1\) in the forest is 0.4 and in the meadow in 0.7. We can easily calculate the expected genotype frequencies within each population, namely

<table>
<thead>
<tr>
<th></th>
<th>(A_1A_1)</th>
<th>(A_1A_2)</th>
<th>(A_2A_2)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Forest</td>
<td>0.16</td>
<td>0.48</td>
<td>0.36</td>
</tr>
<tr>
<td>Meadow</td>
<td>0.49</td>
<td>0.42</td>
<td>0.09</td>
</tr>
</tbody>
</table>

\(^1\)Those of you who’ve been in EEB for a while will know that these are probably different species, but humor me, and forget that you know that.

© 2001-2017 Kent E. Holsinger
Suppose, however, we were to consider a combined population consisting of 100 individuals from the forest subpopulation and 100 individuals from the meadow subpopulation. Then we’d get the following:

<table>
<thead>
<tr>
<th></th>
<th>$A_1A_1$</th>
<th>$A_1A_2$</th>
<th>$A_2A_2$</th>
</tr>
</thead>
<tbody>
<tr>
<td>From forest</td>
<td>16</td>
<td>48</td>
<td>36</td>
</tr>
<tr>
<td>From meadow</td>
<td>49</td>
<td>42</td>
<td>9</td>
</tr>
<tr>
<td>Total</td>
<td>65</td>
<td>90</td>
<td>45</td>
</tr>
</tbody>
</table>

So the frequency of $A_1$ is $(2(65) + 90)/(2(65 + 90 + 45)) = 0.55$. Notice that this is just the average allele frequency in the two subpopulations, i.e., $(0.4 + 0.7)/2$. Since each subpopulation has genotypes in Hardy-Weinberg proportions, you might expect the combined population to have genotypes in Hardy-Weinberg proportions, but if you did you’d be wrong. Just look.

<table>
<thead>
<tr>
<th></th>
<th>$A_1A_1$</th>
<th>$A_1A_2$</th>
<th>$A_2A_2$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Expected (from $p = 0.55$)</td>
<td>(0.3025)200</td>
<td>(0.4950)200</td>
<td>(0.2025)200</td>
</tr>
<tr>
<td></td>
<td>60.5</td>
<td>99.0</td>
<td>40.5</td>
</tr>
<tr>
<td>Observed (from table above)</td>
<td>65</td>
<td>90</td>
<td>45</td>
</tr>
</tbody>
</table>

The expected and observed don’t match, even though there is random mating within both subpopulations. They don’t match because there isn’t random mating in the combined population. Forest lacewings choose mates at random from other forest lacewings, but they never mate with a meadow lacewing (and vice versa). Our sample includes two populations that don’t mix. This is an example of what’s know as the Wahlund effect [7].

**The algebraic development**

You should know by now that I’m not going to be satisfied with a numerical example. I now feel the need to do some algebra to describe this situation a little more generally.

Suppose we know allele frequencies in $k$ subpopulations.\(^3\) Let $p_i$ be the frequency of $A_1$ in the $i$th subpopulation. Then if we assume that all subpopulations contribute equally to combined population,\(^4\) we can calculate expected and observed genotype frequencies the way we did above:

---

\(^2\)If we ignore sampling error.

\(^3\)For the time being, I’m going to assume that we know the allele frequencies without error, i.e., that we didn’t have to estimate them from data. We’ll deal with real life, i.e., how we can detect the Wahlund effect when we have to *estimate* allele frequencies from data, a little later.

\(^4\)We’d get the same result by relaxing this assumption, but the algebra gets messier, so why bother?
where $\bar{p} = \frac{\sum p_i}{k}$ and $\bar{q} = 1 - \bar{p}$. Now

$$\frac{1}{k} \sum p_i^2 = \frac{1}{k} \sum (p_i - \bar{p} + \bar{p})^2$$

(1)

$$= \frac{1}{k} \sum ((p_i - \bar{p})^2 + 2\bar{p}(p_i - \bar{p}) + \bar{p}^2)$$

(2)

$$= \frac{1}{k} \sum (p_i - \bar{p})^2 + \bar{p}^2$$

(3)

$$= \text{Var}(p) + \bar{p}^2$$

(4)

Similarly,

$$\frac{1}{k} \sum 2p_iq_i = 2\bar{pq} - 2\text{Var}(p)$$

(5)

$$\frac{1}{k} \sum q_i^2 = \bar{q}^2 + \text{Var}(p)$$

(6)

Since $\text{Var}(p) \geq 0$ by definition, with equality holding only when all subpopulations have the same allele frequency, we can conclude that

- Homozygotes will be more frequent and heterozygotes will be less frequent than expected based on the allele frequency in the combined population.

- The magnitude of the departure from expectations is directly related to the magnitude of the variance in allele frequencies across populations, $\text{Var}(p)$.

- The effect will apply to any mixing of samples in which the subpopulations combined have different allele frequencies.\(^5\)

- The same general phenomenon will occur if there are multiple alleles at a locus, although it is possible for one or a few heterozygotes to be more frequent than expected if there is positive covariance in the constituent allele frequencies across populations.\(^6\)

\(^5\)For example, if we combine samples from different years or across age classes of long-lived organisms, we may see a deficiency of heterozygotes in the sample purely as a result of allele frequency differences across years. Remember that I told you one of the assumptions underlying derivation of the Hardy-Weinberg principle is that generations are non-overlapping. This is why.

\(^6\)If you’re curious about this, feel free to ask, but I’ll have to dig out my copy of Li [4] to answer. I don’t carry those details around in my head.
• The effect is analogous to inbreeding. Homozygotes are more frequent and heterozygotes are less frequent than expected.\footnote{And this is what we predicted when we started.}

To return to our earlier numerical example:

\[
\text{Var}(p) = \left( (0.4 - 0.55)^2 + (0.7 - 0.55)^2 \right) / 2 \quad (7)
\]
\[
\text{Var}(p) = 0.0225 \quad (8)
\]

<table>
<thead>
<tr>
<th></th>
<th>Expected</th>
<th>Observed</th>
</tr>
</thead>
<tbody>
<tr>
<td>A₁A₁</td>
<td>0.3025</td>
<td>+ 0.0225</td>
</tr>
<tr>
<td>A₁A₂</td>
<td>0.4950</td>
<td>- 2(0.0225)</td>
</tr>
<tr>
<td>A₂A₂</td>
<td>0.2025</td>
<td>+ 0.0225</td>
</tr>
</tbody>
</table>

**Wright’s F-statistics**

One limitation of the way I’ve described things so far is that Var(\(p\)) doesn’t provide a convenient way to compare population structure from different samples. Var(\(p\)) can be much larger if both alleles are about equally common in the whole sample than if one occurs at a mean frequency of 0.99 and the other at a frequency of 0.01. Moreover, if you stare at equations (4)–(6) for a while, you begin to realize that they look a lot like some equations we’ve already encountered. Namely, if we were to define \(F_{st}\)\footnote{The reason for the subscript will become apparent later. It’s also very important to notice that I’m defining \(F_{ST}\) here in terms of the population parameters \(p\) and Var(\(p\)). Again, we’ll return to the problem of how to estimate \(F_{ST}\) from data a little later.} as Var(\(p\))/\(\bar{p}\bar{q}\), then we could rewrite equations (4)–(6) as

\[
\frac{1}{k} \sum p_i^2 = \bar{p}^2 + F_{st} \bar{p}\bar{q} \quad (9)
\]
\[
\frac{1}{k} \sum 2p_iq_i = 2\bar{p}\bar{q}(1 - F_{st}) \quad (10)
\]
\[
\frac{1}{k} \sum q_i^2 = \bar{q}^2 + F_{st} \bar{p}\bar{q} \quad (11)
\]

And it’s not even completely artificial to define \(F_{st}\) the way I did. After all, the effect of geographic structure is to cause matings to occur among genetically similar individuals. It’s rather like inbreeding. Moreover, the extent to which this local mating matters depends on the extent to which populations differ from one another. \(\bar{p}\bar{q}\) is the maximum allele frequency
variance possible, given the observed mean frequency. So one way of thinking about $F_{st}$ is that it measures the amount of allele frequency variance in a sample relative to the maximum possible.\textsuperscript{9}

There may, of course, be inbreeding within populations, too. But it’s easy to incorporate this into the framework, too.\textsuperscript{10} Let $H_i$ be the actual heterozygosity in individuals within subpopulations, $H_s$ be the expected heterozygosity within subpopulations assuming Hardy-Weinberg within populations, and $H_t$ be the expected heterozygosity in the combined population assuming Hardy-Weinberg over the whole sample.\textsuperscript{11} Then thinking of $f$ as a measure of departure from Hardy-Weinberg and assuming that all populations depart from Hardy-Weinberg to the same degree, i.e., that they all have the same $f$, we can define

$$F_{it} = 1 - \frac{H_i}{H_t}$$

Let’s fiddle with that a bit.

$$1 - F_{it} = \frac{H_i}{H_t}$$

$$= \left(\frac{H_i}{H_s}\right)\left(\frac{H_s}{H_t}\right)$$

$$= (1 - F_{is})(1 - F_{st})$$

where $F_{is}$ is the inbreeding coefficient within populations, i.e., $f$, and $F_{st}$ has the same definition as before.\textsuperscript{12} $H_t$ is often referred to as the genetic diversity in a population. So another way of thinking about $F_{st} = (H_t - H_s)/H_t$ is that it’s the proportion of the diversity in the sample that’s due to allele frequency differences among populations.

\textsuperscript{9}I say “one way”, because there are several other ways to talk about $F_{st}$, too. But we won’t talk about them until later.

\textsuperscript{10}At least it’s easy once you’ve been shown how.

\textsuperscript{11}Please remember that we’re assuming we know those frequencies exactly. In real applications, of course, we’ll estimate those frequencies from data, so we’ll have to account for sampling error when we actually try to estimate these things. If you’re getting the impression that I think the distinction between allele frequencies as parameters, i.e., the real allele frequency in the population, and allele frequencies as estimates, i.e., the sample frequencies from which we hope to estimate the parameters, is really important, you’re getting the right impression.

\textsuperscript{12}It takes a fair amount of algebra to show that this definition of $F_{st}$ is equivalent to the one I showed you before, so you’ll just have to take my word for it.
F statistics

We’ve now seen the principles underlying Wright’s F-statistics. I should point out that Gustave Malécot developed very similar ideas at about the same time as Wright, but since Wright’s notation stuck,\textsuperscript{13} population geneticists generally refer to statistics like those we’ve discussed as Wright’s F-statistics.\textsuperscript{14}

Neither Wright nor Malécot worried too much about the problem of estimating F-statistics from data. Both realized that any inferences about population structure are based on a sample and that the characteristics of the sample may differ from those of the population from which it was drawn, but neither developed any explicit way of dealing with those differences. Wright develops some very \textit{ad hoc} approaches in his book [11], but they have been forgotten, which is good because they aren’t very satisfactory and they shouldn’t be used. There are now three reasonable approaches available:\textsuperscript{15}

1. Nei’s G-statistics,
2. Weir and Cockerham’s $\theta$-statistics, and
3. A Bayesian analog of $\theta$.\textsuperscript{16}

An example from \textit{Isotoma petraea}

To make the differences in implementation and calculation clear, I’m going to use data from 12 populations of \textit{Isotoma petraea} in southwestern Australia surveyed for genotype at \textit{GOT–1} [3] as an example throughout these discussions (Table 1).

Let’s ignore the sampling problem for a moment and calculate the F-statistics as if we had observed the population allele frequencies without error. They’ll serve as our baseline for comparison.

\[
\bar{p} = 0.8888 \\
\text{Var}(p) = 0.02118 \\
F_{st} = 0.2143
\]

\textsuperscript{13}Probably because he published in English and Malécot published in French.

\textsuperscript{14}The Hardy-Weinberg proportions should probably be referred to as the Hardy-Weinberg-Castle proportions too, since Castle pointed out the same principle. For some reason, though, his demonstration didn’t have the impact that Hardy’s and Weinberg’s did. So we generally talk about the Hardy-Weinberg principle.

\textsuperscript{15}And as we’ll soon see, I’m not too crazy about one of these three. To my mind, there are really only two approaches that anyone should consider.

\textsuperscript{16}These is, as you have probably already guessed, my personal favorite. We’ll talk about it next time.
Table 1: Genotype counts at the $GOT - 1$ locus in *Isotoma petraea* (from [3]).

</table>

Individual heterozygosity  =  $(0.0000 + 0.1500 + 0.1000 + 0.0000 + 0.0000 + 0.1667 + 0.1000 + 0.0909 + 0.0000 + 0.0000 + 1.0000 + 0.0000)/12$

  = 0.1340

Expected heterozygosity   =  $2(0.8888)(1 - 0.8888)$

  = 0.1976

$F_{it}$  =  $1 - \frac{\text{Individual heterozygosity}}{\text{Expected heterozygosity}}$

  =  $1 - \frac{0.1340}{0.1976}$

  = 0.3221

$1 - F_{it}$  =  $(1 - F_{is})(1 - F_{st})$

$F_{is}$  =  $\frac{F_{it} - F_{st}}{1 - F_{st}}$

  =  $\frac{0.3221 - 0.2143}{1 - 0.2143}$

  = 0.1372
Summary

Correlation of gametes due to inbreeding within subpopulations ($F_{is}$): 0.1372
Correlation of gametes within subpopulations ($F_{st}$): 0.2143
Correlation of gametes in sample ($F_{it}$): 0.3221

Why do I refer to them as the “correlation of gametes . . .”? There are two reasons:

1. That’s the way Wright always referred to and interpreted them.
2. We can define indicator variables $x_{ijk} = 1$ if the $i$th allele in the $j$th individual of population $k$ is $A_1$ and $x_{ijk} = 0$ if that allele is not $A_1$. This may seem like a strange thing to do, but the Weir and Cockerham approach to $F$-statistics described below uses just such an approach. If we do this, then the definitions for $F_{is}$, $F_{st}$, and $F_{it}$ follow directly.\(^{17}\)

Notice that $F_{is}$ could be negative, i.e., there could be an excess of heterozygotes within populations ($F_{is} < 0$). Notice also that we’re implicitly assuming that the extent of departure from Hardy-Weinberg proportions is the same in all populations. Equivalently, we can regard $F_{is}$ as the average departure from Hardy-Weinberg proportions across all populations.

Statistical expectation and unbiased estimates

So far I’ve assumed that we know the allele frequencies without error, but of course that’s never the case unless we’ve created experimental populations. We are always taking a sample from a population and inferring — estimating — allele frequencies from our sample. Similarly, we are estimating $F_{ST}$ and our estimate of $F_{ST}$ needs to take account of the imprecision in the allele frequency estimates on which it was based. To understand one approach to dealing with this uncertainty I need to introduce two new concepts: statistical expectation and unbiased estimates.

The concept of statistical expectation is actually quite an easy one. It is an arithmetic average, just one calculated from probabilities instead of being calculated from samples. So, for example, let $P(k|p)$ be the probability that we find $k$ $A_1$ alleles in our sample given that the allele frequency in the population is $p$. Then the expected number of $A_1$ alleles in our sample is just

$$E(k) = \sum_{k=1}^{n} kP(k)$$

\(^{17}\)See [8] for details.
where \( n \) is the total number of alleles in our sample.\(^{18}\)

Now consider the expected value of our sample estimate of the population allele frequency, \( \hat{p} = k/n \), where \( k \) now refers to the number of \( A_1 \) alleles we actually found.

\[
E(\hat{p}) = E\left(\sum_{k=1}^{n} \frac{k}{n}\right) \\
= \sum_{k=1}^{n} \frac{k}{n} P(k) \\
= \frac{1}{n} \left(\sum_{k=1}^{n} kP(k)\right) \\
= \frac{1}{n} (np) \\
= p \ .
\]

Because \( E(\hat{p}) = p \), \( \hat{p} \) is said to be an *unbiased estimate* of \( p \).\(^{19}\) When an estimate is unbiased it means that if we were to repeat the sampling experiment an infinite number of times and to take the average of the estimates, the average of those values would be equal to the (unknown) parameter value.

What about estimating the frequency of heterozygotes within a population? The obvious estimator is \( \tilde{H} = 2\hat{p}(1 - \hat{p}) \). Well,

\[
E(\tilde{H}) = E\left(2\hat{p}(1 - \hat{p})\right) \\
= 2 \left(E(\hat{p}) - E(\hat{p}^2)\right) \\
= TAMO \\
= \left(\frac{n-1}{n}\right)2p(1-p) \ .
\]

Because \( E(\tilde{H}) \neq 2p(1 - p) \), \( \tilde{H} \) is a *biased estimate* of \( 2p(1 - p) \). If we set \( \hat{H} = (n/(n-1))\tilde{H} \), however, \( \hat{H} \) is an unbiased estimator of \( 2p(1 - p) \).\(^{20}\)

\(^{18}\)\( P(k) = \binom{N}{k}p^k(1-p)^{N-k} \). The algebra in getting from the first line to the second is a little complicated, but feel free to ask me about it if you’re interested.

\(^{19}\)Notice that I’m using a hat here to refer to a statistical estimate. Remember when I told you I’d be using hats for a couple of different purposes? Well, this is the second one.

\(^{20}\)If you’re wondering how I got from the second equation for \( \tilde{H} \) to the last one, ask me about it or read
If you’ve ever wondered why you typically divide the sum of squared deviations about the mean by \( n - 1 \) instead of \( n \) when estimating the variance of a sample, this is why. Dividing by \( n \) gives you a (slightly) biased estimator.

**The gory details**

Starting where we left off above:

\[
E(\bar{H}) = 2 \left( (E\hat{p}) - E(\hat{p}^2) \right) = 2 \left( p - E \left( \left( \frac{k}{n} \right)^2 \right) \right),
\]

where \( k \) is the number of \( A_1 \) alleles in our sample and \( n \) is the sample size.

\[
E \left( \left( \frac{k}{n} \right)^2 \right) = \sum \left( \frac{k}{n} \right)^2 P(k) = \frac{1}{n} \sum k^2 P(k) = \frac{1}{n} \left( \text{Var}(k) + \bar{k}^2 \right) = \frac{1}{n} \left( np(1 - p) + n^2 p^2 \right) = p(1 - p)/n + p^2.
\]

Substituting this back into the equation above yields the following:

\[
E(\bar{H}) = 2 \left( p - \left( \frac{p(1 - p)}{n} + p^2 \right) \right) = 2 \left( p(1 - p) - \frac{p(1 - p)}{n} \right) = \frac{1 - 1/n}{2} 2p(1 - p) = \frac{(n - 1)/n}{2} 2p(1 - p).
\]

**Corrections for sampling error**

There are two sources of allele frequency difference among subpopulations in our sample: (1) real differences in the allele frequencies among our sampled subpopulations and (2) differences the gory details section that follows. TAMO is short for “Then a miracle occurs.” You’ll see that repeatedly this semester.

21 Skip this part unless you are really, really interested in how I got from the second equation to the third equation in the last paragraph. This is more likely to confuse you than help unless you know that the variance of a binomial sample is \( np(1 - p) \) and that \( E(k^2) = \text{Var}(p) + p^2 \).
that arise because allele frequencies in our samples differ from those in the subpopulations from which they were taken.\textsuperscript{22}

**Nei’s \( G_{st} \)**

Nei and Chesser \cite{5} described one approach to accounting for sampling error. So far as I’ve been able to determine, there aren’t any currently supported programs\textsuperscript{23} that calculate the bias-corrected versions of \( G_{st} \).\textsuperscript{24} I calculated the results in Table 2 by hand.

The calculations are tedious, which is why you’ll want to find some way of automating the calculations if you want to do them.\textsuperscript{25}

\[
H_i = 1 - \frac{1}{N} \sum_{k=1}^{N} \sum_{i=1}^{m} X_{kii}
\]

\[
H_s = \frac{\tilde{n}}{\tilde{n} - 1} \left[ 1 - \sum_{i=1}^{m} \bar{x}_i^2 - \frac{H_I}{2\tilde{n}} \right]
\]

\[
H_t = 1 - \sum_{i=1}^{m} \bar{x}_i^2 + \frac{H_S}{\tilde{n}} - \frac{H_I}{2\tilde{n}N}
\]

where we have \( N \) subpopulations, \( \bar{x}_i^2 = \sum_{k=1}^{N} x_{ki}^2 / N \), \( \bar{x}_i = \sum_{k=1}^{N} x_{ki} / N \), \( \tilde{n} \) is the harmonic mean of the population sample sizes, i.e., \( \tilde{n} = \frac{1}{\sum_{k=1}^{N} \frac{1}{n_k}} \), \( X_{kii} \) is the frequency of genotype \( A_iA_i \) in population \( k \), \( x_{ki} \) is the frequency of allele \( A_i \) in population \( k \), and \( n_k \) is the sample size from population \( k \). Recall that

\[
F_{is} = 1 - \frac{H_i}{H_s}
\]

\[
F_{st} = 1 - \frac{H_s}{H_t}
\]

\[
F_{it} = 1 - \frac{H_i}{H_t}
\]

\textsuperscript{22}There’s actually a third source of error that we’ll get to in a moment. The populations we’re sampling from are the product of an evolutionary process, and since the populations aren’t of infinite size, drift has played a role in determining allele frequencies in them. As a result, if we were to go back in time and re-run the evolutionary process, we’d end up with a different set of real allele frequency differences. We’ll talk about this more in just a moment when we get to Weir and Cockerham’s statistics.

\textsuperscript{23}\textbf{Popgene} estimates \( G_{st} \), but I don’t think it’s been updated since 2000. \textbf{FSTAT} also estimates gene diversities, but the most recent version is from 2002.

\textsuperscript{24}There’s a reason for this that we’ll get to in a moment. It’s alluded to in the last footnote.

\textsuperscript{25}It is also one big reason why most people use Weir and Cockerham’s \( \theta \). There’s readily available software that calculates it for you.
**Weir and Cockerham’s θ**

Most, if not all, packages available now that estimate $F_{ST}$ provide estimates of $\theta$. The most important difference between $\theta$ and $G_{st}$ and the reason why $G_{st}$ has fallen into disuse is that $G_{st}$ ignores an important source of sampling error that $\theta$ incorporates.

In many applications, especially in evolutionary biology, the subpopulations included in our sample are not an exhaustive sample of all populations. Moreover, even if we have sampled from every population there is now, we may not have sampled from every population there ever was. And even if we’ve sampled from every population there ever was, we know that there are random elements in any evolutionary process. Thus, if we could run the clock back and start it over again, the genetic composition of the populations we have might be rather different from that of the populations we sampled. In other words, our populations are, in many cases, best regarded as a random sample from a much larger set of populations that could have been sampled.

**Even more gory details**27

Let $x_{mn,i}$ be an indicator variable such that $x_{mn,i} = 1$ if allele $m$ from individual $n$ is of type $i$ and is 0 otherwise. Clearly, the sample frequency $\hat{p}_i = \frac{1}{2N} \sum_{m=1}^{2} \sum_{n=1}^{N} x_{mn,i}$, and $E(\hat{p}_i) = p_i$, $i = 1 \ldots A$. Assuming that alleles are sampled independently from the population

$$E(x_{mn,i}^2) = p_i$$
$$E(x_{mn,i}x_{m'n,i}) = E(x_{mn,i}x_{m'n,i}) = p_i^2 + \sigma_{x_{mn,i}x_{m'n,i}}$$

where $\sigma_{x_{mn,i}x_{m'n,i}}$ is the intraclass covariance for the indicator variables and

$$\theta = \frac{\sigma_{x_{mi}}^2}{p_i(1 - p_i)}$$ (12)

is the scaled among population variance in allele frequency in the populations from which this population was sampled. Using (12) we find after some algebra

$$\sigma_{\hat{p}_i}^2 = p_i(1 - p_i)\theta + \frac{p_i(1 - p_i)(1 - \theta)}{2N}$$.

26We also talk a bit more about how $F$-statistics can be used. If you just can’t get enough of this, I suggest you take a look at Verity and Nichols [6]. They provide a really solid analysis of $F_{ST}$, $G_{ST}$, and some related statistics.

27This is even worse than the last time. I include it for completeness only. I really don’t expect anyone (unless they happen to be a statistician) to be able to understand these details.
Table 2: Comparison of Wright’s $F$-statistics when ignoring sampling effects with Nei’s $G_{ST}$ and Weir and Cockerham’s $\theta$.

<td>$\theta$</td>
<td></td>
</tr>
</tbody>
</table>

The hat on $\hat{\sigma}^2_{p_i}$ indicates the sample variance of allele frequencies among populations. A natural estimate for $\theta$ emerges using the method of moments when an analysis of variance is applied to indicator variables derived from samples representing more than one population.

**Applying $G_{st}$ and $\theta$**

If we return to the data that motivated this discussion, these are the results we get from analyses of the $GOT – 1$ data from *Isotoma petraea* (Table 1). But first a note on how you’ll see statistics like this reported in the literature. It can get a little confusing, because of the different symbols that are used. Sometimes you’ll see $F_{is}, F_{st},$ and $F_{it}$. Sometimes you’ll see $f, \theta,$ and $F$. And it will seem as if they’re referring to similar things. That’s because they are. They’re really just different symbols for the same thing (see Table 3). Strictly speaking the symbols in Table 3 are the parameters, i.e., values in the population that we try to estimate. We should put hats over any values estimated from data to indicate that they are estimates of the parameters, not the parameters themselves. But we’re usually a bit sloppy, and everyone knows that we’re presenting estimates, so we usually leave off the hats.
An example from Wright

Hierarchical analysis of variation in the frequency of the Standard chromosome arrangement of *Drosophila pseudoobscura* in the western United States (data from [1], analysis from [12]). Wright uses his rather peculiar method of accounting for sampling error. I haven’t gone back to the original data and used a more modern method of analysis.28

66 populations (demes) studied. Demes are grouped into eight regions. The regions are grouped into four primary subdivisions.

Results

| Correlation of gametes within individuals relative to regions ($F_{IR}$): | 0.0444 |
| Correlation of gametes within regions relative to subdivisions ($F_{RS}$): | 0.0373 |
| Correlation of gametes within subdivisions relative to total ($F_{ST}$): | 0.1478 |
| Correlation of gametes in sample ($F_{IT}$): | 0.2160 |

\[1 - F_{IT} = (1 - F_{IR})(1 - F_{RS})(1 - F_{ST})\]

Interpretation

There is relatively little inbreeding within regions ($F_{IR} = 0.04$) and relatively little genetic differentiation among regions within subdivisions ($F_{RS} = 0.04$). There is, however, substantial genetic differentiation among the subdivisions ($F_{ST} = 0.15$).

Thus, an explanation for the chromosomal diversity that predicted great local differentiation and little or no differentiation at a large scale would be inconsistent with these observations.

References

28Sounds like it might be a good project, doesn’t it? We’ll see.
