Analysis of molecular variance (AMOVA)

Introduction

We’ve already encountered \( \pi \), the nucleotide diversity in a population, namely

\[
\pi = \sum_{ij} x_i x_j \delta_{ij},
\]

where \( x_i \) is the frequency of the \( i \)th haplotype and \( \delta_{ij} \) is the fraction of nucleotides at which haplotypes \( i \) and \( j \) differ.\(^1\) It shouldn’t come to any surprise to you that just as there is interest in partitioning diversity within and among populations when we’re dealing with simple allelic variation, i.e., Wright’s \( F \)-statistics, there is interest in partitioning diversity within and among populations when we’re dealing with nucleotide sequence or other molecular data. The approach I’m going to describe is known as Analysis of Molecular VAriance (AMOVA) [1]. We’ll see later that AMOVA can be used very generally to partition variation when there is a distance we can use to describe how different alleles are from one another, but for now, let’s stick with nucleotide sequence data and think of \( \delta_{ij} \) simply as the fraction of nucleotide sites at which two sequences differ.

Analysis of molecular variance (AMOVA)

The notation now becomes just a little bit more complicated. We will now use \( x_{ik} \) to refer to the frequency of the \( i \)th haplotype in the \( k \)th population. Then

\[
x_i = \frac{1}{K} \sum_{k=1}^{K} x_{ik}
\]

\(^1\)When I introduced nucleotide diversity before, I defined \( \delta_{ij} \) as the number of nucleotides that differ between haplotypes \( i \) and \( j \). It’s a little easier for what follows if we think of it as the fraction of nucleotides at which they differ instead. It’s really easy to convert between the two. If \( \delta^*ij \) is the number of nucleotides that differ between haplotypes \( i \) and \( j \) and \( N \) is the length of the haplotype sequence, then \( \delta_{ij} = \delta^*ij/N \). Of course, if we wanted to get fancy we could use a Bayesian approach to estimate \( \delta_{ij} \), but we’ll avoid that complication in what follows.

© 2001-2019 Kent E. Holsinger
is the mean frequency of haplotype \( i \) across all populations, where \( K \) is the number of populations. We can now define

\[
\pi_t = \sum_{ij} x_i x_j \delta_{ij}
\]

\[
\pi_s = \frac{1}{K} \sum_{k=1}^{K} \sum_{ij} x_{ik} x_{jk} \delta_{ij},
\]

where \( \pi_t \) is the nucleotide sequence diversity across the entire set of populations and \( \pi_s \) is the average nucleotide sequence diversity within populations. Then we can define

\[
\Phi_{st} = \frac{\pi_t - \pi_s}{\pi_t},
\]

which is the direct analog of Wright’s \( F_{st} \) for nucleotide sequence diversity. Why? Well, that requires you to remember stuff we covered about two months ago.

To be a bit more specific, refer back to the online notes\(^2\) or to Chapter 4 in the book version of the notes\(^3\). If you do, you’ll see that we defined

\[
F_{IT} = 1 - \frac{H_i}{H_t},
\]

where \( H_i \) is the average heterozygosity in individuals and \( H_t \) is the expected panmictic heterozygosity. Defining \( H_s \) as the average panmictic heterozygosity within populations, we then observed that

\[
1 - F_{IT} = \frac{H_i}{H_t} = \frac{H_i H_s}{H_s H_t} = (1 - F_{IS})(1 - F_{ST})
\]

\[
1 - F_{ST} = \frac{1 - F_{IT}}{1 - F_{IS}}
\]

\[
F_{ST} = \frac{(1 - F_{IS}) - (1 - F_{IT})}{1 - F_{IS}} = \frac{(H_i/H_s) - (H_i/H_t)}{H_i/H_s} = 1 - \frac{H_s}{H_t}.
\]

\(^3\)https://figshare.com/articles/Lecture_notes_in_population_genetics/100687
In short, another way to think about $F_{ST}$ is

$$F_{ST} = \frac{H_t - H_s}{H_t}.$$ (2)

Now if you compare equation (1) and equation (2), you’ll see the analogy.

So far I’ve motivated this approach by thinking about $\delta_{ij}$ as the fraction of sites at which two haplotypes differ and $\pi_s$ and $\pi_t$ as estimates of nucleotide diversity. But nothing in the algebra leading to equation (1) requires that assumption. Excoffier et al. [1] pointed out that other types of molecular data can easily be fit into this framework. We simply need an appropriate measure of the “distance” between different haplotypes or alleles. Even with nucleotide sequences the appropriate $\delta_{ij}$ may reflect something about the mutational pathway likely to connect sequences rather than the raw number of differences between them. For example, the distance might be a Jukes-Cantor distance or a more general distance measure that accounts for more of the properties we know are associated with nucleotide substitution. The idea is illustrated in Figure 1. Once we have $\delta_{ij}$ for all pairs of haplotypes or alleles in our sample, we can use the ideas lying behind equation (1) to partition diversity — the average distance between randomly chosen haplotypes or alleles — into within and among population components.4 This procedure for partitioning diversity in molecular markers is referred to as an analysis of molecular variance or AMOVA (by analogy with the ubiquitous statistical procedure analysis of variance, ANOVA). Like Wright’s $F$-statistics, the analysis can include several levels in the hierarchy.

**An AMOVA example**

Excoffier et al. [1] illustrate the approach by presenting an analysis of restriction haplotypes in human mtDNA. They analyze a sample of 672 mitochondrial genomes representing two populations in each of five regional groups (Figure 2). They identified 56 haplotypes in that sample. A minimum spanning tree illustrating the relationships and the relative frequency of each haplotype is presented in Figure 3.

It’s apparent from Figure 3 that haplotype 1 is very common. In fact, it is present in substantial frequency in every sampled population. An AMOVA using the minimum spanning network in Figure 3 to measure distance produces the results shown in Table 1. Notice

---

4As with $F$-statistics, the actual estimation procedure is more complicated than I describe here. Standard approaches to AMOVA use method of moments calculations analogous to those introduced by Weir and Cockerham for $F$-statistics [5]. Bayesian approaches are possible, but they are not yet widely available (meaning, in part, that I know how to do it, but I haven’t written the necessary software yet). Gompert et al. [2] describe one approach for Bayesian AMOVA from pooled DNA sequences obtained from high-throughput sequencing.

Table 1: AMOVA results for the human mtDNA sample (from [1]).

that there is relatively little differentiation among populations within the same geographical region (Φ_{SC} = 0.044). There is, however, substantial differentiation among regions (Φ_{CT} = 0.220). In fact, differences among populations in different regions is responsible for nearly all of the differences among populations (Φ_{ST} = 0.246). Notice also that Φ-statistics follow the same rules as Wright’s F-statistics, namely

\[
1 - \Phi_{ST} = (1 - \Phi_{SC})(1 - \Phi_{CT})
\]

or

\[
0.754 = (0.956)(0.78)
\]

within the bounds of rounding error.⁵

⁵There wouldn’t be any rounding error if we had access to the raw data.
An extension

As you may recall, Slatkin [4] pointed out that there is a relationship between coalescence time and $F_{st}$. Namely, if mutation is rare then

$$F_{st} \approx \frac{\bar{t} - \bar{t}_0}{\bar{t}},$$

where $\bar{t}$ is the average time to coalescence for two genes drawn at random without respect to population and $\bar{t}_0$ is the average time to coalescence for two genes drawn at random from the same populations. Results in [3] show that when $\delta_{ij}$ is linearly proportional to the time since two sequences have diverged, $\Phi_{st}$ is a good estimator of $F_{st}$ when $F_{st}$ is thought of as a measure of the relative excess of coalescence time resulting from dividing a species into several population. This observation suggests that the combination of haplotype frequency differences and evolutionary distances among haplotypes may provide insight into the evolutionary relationships among populations of the same species.
